A B S T R A C T

In this study, we contrasted major secondary inorganic species and processes responsible for submicron particle formation (SPF) events in the boundary layer (BL) and free troposphere (FT) over the Korean Peninsula during Korea-United States Air Quality (KORUS-AQ) campaign (May–June 2016) using aircraft observations. The number concentration of ultrafine particles with diameters between 3 nm and 10 nm ($N_{3-10}$) during the entire KORUS-AQ period reached a peak (7606 ± 12,003 cm$^{-3}$) at below 1 km altitude, implying that the particle formation around the Korean Peninsula primarily occurred in the daytime BL. During the BL SPF case (7 May 2016), the SPF over Seoul metropolitan area was more attributable to oxidation of NO$_2$ rather than SO$_2$-to-sulfate conversion. From the analysis of the relationship between nitrogen oxidation ratio (NOR) and temperature or relative humidity (RH), NOR showed a positive correlation only with temperature. This suggests that homogeneous gas-phase reactions of NO$_2$ with OH or O$_3$ contributed to nitrate formation. From the relationship between $N_{3-10}$ ($>$ 10,000 cm$^{-3}$) and the NOR (or sulfur oxidation ratio) at Olympic Park in Seoul during the entire KORUS-AQ period, it was regarded that the relative importance of nitrogen oxidation was grown as the $N_{3-10}$ increased. During the FT SPF case (31 May 2016) over the yellow sea, the SO$_2$-to-sulfate conversion seemed to influence SPF highly. The sulfate/CO ratio had a positive correlation with both the temperature and RH, suggesting that aqueous-phase pathways as well as gas-phase reactions might be attributable to sulfate formation in the FT. In particular, FT SPF event on 31 May was possibly caused by the direct transport of SO$_2$ precursors from the continent above the shallow marine boundary layer under favorable conditions for FT SPF events, such as decreased aerosol surface area and increased solar radiation.

1. Introduction

Many regions in East Asia, like China or the Korean Peninsula, have suffered from extreme haze events brought on by elevated concentrations of PM$_{2.5}$ (particulate matter with diameters ≤2.5 μm) (Liu et al., 2019; Park et al., 2021). Particularly, secondary inorganic species such as sulfate, nitrate, and ammonium made up a substantial part (about 47%) of PM$_{2.5}$ in Seoul during the Korea-United States Air Quality (KORUS-AQ) campaign (May–June 2016), suggesting that the formation of submicron particles can play a significant role in the occurrence of haze events (Wang et al., 2016; NIER and NASA, 2017; Chu et al., 2020). Because such frequently occurring haze events are widely known to

create adverse effects on human health (Hannah et al., 2019; Jiang et al., 2020; Zeng et al., 2020), it is crucial to determine the characteristics of submicron particle formation (SPF) that are associated with the dominant precursors or possible physical and chemical mechanisms to establish efficient mitigation strategies for secondary inorganic species.

Numerous types of observational evidence have indicated that submicron particles can be produced in the boundary layer (BL) by various precursor gases through complex chemical mechanisms. The formation of sulfate is largely fulfilled in the aqueous surface of aerosol particles or precursor gases through complex chemical mechanisms. The formation of sulfuric acid via gas-phase reactions of sulfur dioxide (SO2) with hydrogen oxide (OH) can also be important for generating sulfate (Sander and Seinfeld, 1976; Ji et al., 2018). Recently, several studies have analyzed new formation particle formation (NPF) events driven by sulfuric acid (H2SO4) precursors at a molecular level. Yao et al. (2018) observed initial clusters of NPF and suggested that H2SO4-dimethylamine (DMA)-water (H2O) nucleation has a crucial role in NPF in megacities of China. Myllys et al. (2019) introduced a molecular-level explanation for nanoparticle production through H2SO4-DMA-ammonia (NH3) cluster formation. For nitrate, dinitrogen pentoxide (N2O5) can act as a reservoir of NO3 during the nighttime, and nitric acid (HNO3) is subsequently formed by heterogeneous hydrolysis of N2O5, which is thermally decomposed and photolysed during the day (Russell et al., 1986; Liu et al., 2020a). While the nighttime chemistry of nitrate episodes can be relatively well understood, the dominant pathways during the daytime are controversial (Tao et al., 2018; Tian et al., 2019).

In addition to the typical gas-phase oxidation of nitrogen dioxide (NO2) with OH or O3 (Richards, 1983; Khoder, 2002; Alexander et al., 2009; Liu et al., 2020b), more complicated reactions such as nitrate formation in cloud water have been proposed (Tao et al., 2018).

Given the favorable conditions for SPF (e.g., reduced surface area or increased solar insolation), the free troposphere (FT) can be a significant origin of the newly formed particles (Song et al., 2010; Rose et al., 2017; Qi et al., 2019; Takegawa et al., 2020). Furthermore, particles formed in the FT can be entrained to the BL, thereby influencing on the air quality of the BL (Kerminen et al., 2018; Takegawa et al., 2020). However, despite the importance of SPF in the FT, few observations in the FT actually exist since they can only be conducted through limited methods, such as mountain-top observations (Bianchi et al., 2016; Shen et al., 2018; Lv et al., 2018). Although SPF events captured by ground-based observation in the mountain-top site can be related to the FT (Rose et al., 2017), they are also often associated with the airmass originated from the BL following the daytime valley wind (Rodriguez et al., 2009; Shen et al., 2016). The characteristics of FT SPF can be similar to the that of BL SPF under the daytime valley breeze, but relatively small amount of condensable vapors can result in the active FT SPF under above-mentioned favorable conditions compared to BL (Takegawa et al., 2020).

Various optical, physical, and chemical properties of aerosols related to SPF in the FT as well as BL were observed through the synergetic use of continuous ground-based observations and twenty research flights over the Korean Peninsula during the KORUS-AQ campaign. Based on the airborne and ground-level observations, we contrasted the major secondary inorganic species and possible processes responsible for SPF events in the BL and FT during the KORUS-AQ campaign. An overview of SPF characteristics based on the vertical profile of the number size distribution during the KORUS-AQ campaign is provided in the Section 3. An analysis of the possible causes during the BL and FT SPF cases of the KORUS-AQ is a characterization that extends to the entire period of KORUS-AQ over the Korean Peninsula are given in Section 4.

2. Measurements and data

In this study, we used measurements collected onboard twenty research flights of the NASA DC-8 aircraft and at a ground station located in Seoul during the KORUS-AQ field campaign. The measured parameters and uncertainties of the instruments are given in Table 1.

ratio was obtained from the NCAR 4-channel NO$_2$O$_3$ chemiluminescence instrument, which induces a chemiluminescent reaction by adding reagent O$_3$ to the sample flow (Weinheimer et al., 1993).

Ground observations were conducted at Olympic Park (37.52° N, 127.12° E; 26 m above mean sea level) in Seoul. The number concentrations of aerosols with diameters greater than 3 nm and 10 nm were derived from the same instruments (CPC-3776 and CPC-3010) used for the airborne measurements (Kim et al., 2020b, 2020c). The concentrations of inorganic species such as sulfate and nitrate in PM$_{2.5}$ were measured by the Monitor for Aerosols & Gases in Ambient Air (MARGA ADI2080), which takes advantage of ion chromatography to separate ions according to their charges (Choi et al., 2019). The SO$_2$ mixing ratio was obtained from the KENTEK SO$_2$ analyzer (MEZUS-110) by applying an ultraviolet fluorescent method (Kim et al., 2020a). Lastly, the NO$_2$ mixing ratio was estimated by the Teledyne T500U CAPS analyzer using a cavity attenuated phase shift (CAPS) technique (Nowlan et al., 2016). More details related to the instrumentation mentioned above can be found in the literature listed in Table 1.

We also used the three-dimensional global chemical transport model, GEOS-Chem (Bey et al., 2001; Oak et al., 2019), for the East Asian region (27.5° N–47.5° N, 107.5° E–137.5° E) to identify the migration of precursors attributable to the SPF events at high altitudes. The model was driven by Goddard Earth Observing System-Forward Processing (GEOS-FP) assimilated meteorology data with a spatial resolution of 0.25° × 0.3125° produced by the NASA Global Modeling and Assimilation Office (GMAO; https://gmao.gsfc.nasa.gov/GMAO_products/). For the anthropogenic emissions, the KORUS-AQ v5 emission inventory was applied, which is based on the Comprehensive Regional Emissions for Atmospheric Transport Experiment (CREATE) inventory developed by Konkuk University (Woo et al., 2012).

3. Results and discussion

3.1. Vertical distribution of aerosol number concentration during the KORUS-AQ campaign

To elaborate on the overall SPF characteristics during the KORUS-AQ campaign, the vertical profile of the number concentration of ultrafine particles with diameters between 3 nm and 10 nm (N$_{\text{CN3-10}}$) was examined. N$_{\text{CN3-10}}$ generally decreased with increasing altitudes, showing a peak of around 7606 ± 12,003 cm$^{-3}$ below 1 km altitude (Fig. 1a), suggesting SPFs around the Korean Peninsula were primarily regarded to occur in the BL rather than the FT. Previous studies reported that NPF frequency in the BL was highest during the springtime in the polluted urban area (Park et al., 2015) as well as relatively clean regional background sites (Kim et al., 2013). Furthermore, NPF occurrence rate during the KORUS-AQ campaign (~63%) was higher than the springtime seasonal mean (Lee et al., 2021), contributing to the BL peak of N$_{\text{CN3-10}}$ in this study. Although the SPF event was observed in the FT over the polluted areas such as urban Beijing and Yangtze River Delta region (Quan et al., 2017; Qi et al., 2019), the averaged vertical profile of N$_{\text{CN3-10}}$ over Korean Peninsula was more consistent to the results from the literatures that reported the active SPF in the BL (Väisänen et al., 2016; Altstätter et al., 2018).

N$_{\text{CN3-10}}$ was generally above 6000 cm$^{-3}$ up to the daytime BL height (~1 km) and rapidly decreased to about 3000 cm$^{-3}$ in the vicinity of 1 km altitude. N$_{\text{CN3-10}}$ decreased even more from an altitude of about 4 km, down to ~1000 cm$^{-3}$. The number densities of aerosols with diameters from 10 nm to 199.5 nm were maintained over ~6000 cm$^{-3}$ from the surface to the daytime BL height (Fig. 1b). A number density of ~3000–4000 cm$^{-3}$ of accumulation-mode particles was observed at the 1–2 km range, possibly due to the influence of long-range transport of aged particles from upwind regions (Yu et al., 2006; Cho et al., 2021). Furthermore, particles in this size range (>50–100 nm) can be potentially activated into cloud condensation nuclei (CCN; Rose et al., 2017). This implied that the formation of low-level clouds below 2 km altitude.
can be highly influenced by vertical distribution of accumulation-mode particles over Korean Peninsula under low horizontal variability of activated CCN during the KORUS-AQ campaign (Park et al., 2020). Meanwhile, the number density of nucleation-mode (~15 nm) particles was over ~10,000 cm\(^{-3}\) near the surface, reflecting frequent particle formation in the BL. Similar to the vertical profile of \(N_{CN3-10}\) (Fig. 1a), the number densities from 10 nm to 199.5 nm (Fig. 1b) indicated almost no particles above ~4 km altitude.

3.2. Observations of SPF events in the boundary layer (BL) and free troposphere (FT)

SPF cases in the BL and FT during the KORUS-AQ campaign were selected to contrast the major secondary inorganic species and possible processes. Although condensable organic vapors can play a significant role in SPF over Korean Peninsula (Choi et al., 2017; Kim et al., 2018), this study focused on the inorganic compounds because the composition of secondary inorganic aerosols was generally larger than that of organic aerosols during the KORUS-AQ campaign (Jordan et al., 2020). Because research flights during the KORUS-AQ campaign were conducted in the daytime, the daytime BL height (~1 km) was considered to determine the BL SPF case (Park et al., 2020). Meanwhile, the meaningful FT altitude in terms of SPF was determined to be from 2 to 4 km, because \(N_{CN3-10}\) dramatically decreased after 4 km altitude (Fig. 1a).

![Fig. 2. BL SPF case (7 May 2016): (a) The flight path in the BL and FT. The SMA is denoted as red circle and \(N_{CN3-10}\) corresponding to the flight path is represented as colour scale. (b) The time series of flight altitude. The light grey line is located at the 1 km, 2 km, 4 km altitudes and the period of BL (<1 km) flight over SMA is shaded as red colour. (c) The time series of \(N_{CN3-10}\). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)](image-url)
3.2.1. BL SPF case: 7 May 2016

During 7 May, the flight route consisted of Seoul-Busan and Seoul-Pohang, and stereoscopic observations were conducted in the Seoul metropolitan area (SMA) three times (i.e., the beginning, middle, and end of the flight). In particular, the observations at altitudes from 2 to 4 km (designated as the FT in this study) were carried out only in the SMA during the day. The defined BL and FT altitudes as well as variation of flight altitude are represented in Fig. 2b. The N\textsubscript{CN2-10} following the flight route was observed to be over ~12,000 cm\textsuperscript{-3} in the BL of the SMA, but negligible N\textsubscript{CN2-10} was measured in the FT (Fig. 2a). Consistently, a considerable aerosol backscatter coefficient (~0.006 km\textsuperscript{-1} sr\textsuperscript{-1}) was only observed below 1 km from the high spectral resolution lidar (HSRL) measurement (not shown). The N\textsubscript{CN2-10} in the BL during 08:00-09:00 local standard time (LST) was as high as about 10,000 cm\textsuperscript{-3} and increased up to 50,000–100,000 cm\textsuperscript{-3} from 10:00 LST by the influence of SPF under the increased solar radiation (Fig. 2c; Chandra et al., 2016).

Overall, 7 May was designated as a BL SPF case generated in the SMA in this study. Fig. 3 displays the time series of major secondary inorganic species and their precursors during the BL SPF case, which are largely related to the submicron particles in East Asia. Note that the increase of secondary inorganic species cannot be only attributable to the formation of submicron particles. For example, the simultaneous increase in secondary inorganic aerosols in the morning (about 08:18 LST) can be regarded as a result influenced by the transported plume or primary emission, because the increase occurred under a relatively low N\textsubscript{CN2-10} (~10,000 cm\textsuperscript{-3}) condition during 7 May. The SO\textsubscript{2} mixing ratio in the BL of the SMA was maintained at a range lower than about 5000 pptv during the day; however, the sulfate concentration of the BL during the day did not show a clear increase even when the SO\textsubscript{2} mixing ratio increased slightly except for a few minutes after 10:00 LST. The increase of SO\textsubscript{2} mixing ratio was 2–3 times lower than that of NO\textsubscript{2} right after 10:00 LST, considering the similar scale of the variation between them during the KORUS-AQ campaign (Kim et al., 2020a). A sharp increase in the nitrate concentration can be attributable to the oxidation of NO\textsubscript{2} with OH or O\textsubscript{3}. The formation of oxidation products (HNO\textsubscript{3}; nitric acid) could also be identified. Thus, the SPF over the SMA can be more attributable to the oxidation of NO\textsubscript{2} with OH or O\textsubscript{3} rather than to SO\textsubscript{2}-to-sulfate conversion.

Gas-phase reaction rates can positively be correlated with the temperature according to the Arrhenius equation (De Persis et al., 2004; Seinfeld and Pandis, 2016), while the aqueous-phase processes are known to occur more actively under humid environmental condition (Wu et al., 2019; Seinfeld and Pandis, 2016). Based on the theories, we can roughly look into the formation mechanisms of major secondary inorganic species during the case considered herein. It is worth to mentioning that the above-mentioned period unrelated to SPF (around 8:16–8:27 LST) was excluded from the analysis. The nitrogen and sulfur oxidation ratios (NOR and SOR) were defined as the molar fraction of nitrate and sulfate: NOR = nNO\textsubscript{3}/(nNO\textsubscript{3} + nNO\textsubscript{2}), SOR = nSO\textsubscript{4}/(nSO\textsubscript{4}/3 + nSO\textsubscript{2}/3) (Li et al., 2018; Tian et al., 2019). The NOR during the BL SPF case was positively correlated with the air temperature (r = 0.69 with p = 0.006; Fig. 4a) rather than RH (r = 0.30 with p = 0.19; Fig. 4b). Given that a positive correlation with air temperature can related to the gas-phase pathways, this suggested that homogeneous gas-phase reactions of NO\textsubscript{2} with OH or O\textsubscript{3} contributed to nitrate formation over SMA. Although the primary pathways controlling the daytime nitrate formation remain controversial (Tao et al., 2018), many previous studies have reported that gas-phase pathways are predominant for...
nitrate formation during the daytime (Khoder, 2002; Shen et al., 2020; Liu et al., 2020b).

By considering the abrupt increase of $\text{N}_\text{CN3}\text{–10}$ as an indicator of recent SPF event (Kulmala et al., 2004; Crumeyrolle et al., 2010; Kim et al., 2014), the relationship between $\text{N}_\text{CN3}\text{–10}$ (> 10,000 cm$^{-3}$) and NOR (or SOR) measured hourly at Olympic Park in Seoul was inspected to characterize SPF in Seoul during the period of entire KORUS-AQ campaign (12 May to 10 June, Fig. 5). Because several previous studies have reported that the oxidation of $\text{SO}_2$ to sulfate through sulfuric acid formation could play a dominant role in the SPF in the urban boundary layer over East Asia (Zhang et al., 2004; Yue et al., 2010; Yao et al., 2018), many schemes largely deal with the formation of submicron particles as a function of the concentration of sulfuric acid (Kazil and Lovejoy, 2007; Kürten, 2019). Our analysis suggests that the absolute SOR was generally higher than NOR, indicating that the oxidation of sulfur could be more dominant than that of nitrogen during the KORUS-AQ campaign. Meanwhile, NOR had a positive correlation with $\text{N}_\text{CN3}\text{–10}$ ($r = 0.45$; Fig. 5b) but SOR had little ($r = 0.30$), which suggests that the relative importance of nitrogen oxidation grew compared to sulfur oxidation when the $\text{N}_\text{CN3}\text{–10}$ increased. This result is consistent with previous intensive field experiments over the polluted environment (Young et al., 2016; Li et al., 2018; Chen et al., 2020). For example, Young et al. (2016) revealed that ammonium nitrate was dominant among the constituent of PM$_{1}$ at polluted urban environment during Deriving Information on Surface Conditions from Column and Vertically Resolved Observations Relevant to Air Quality (DISCOVER-AQ) campaign.

### 3.2.2. FT SPF case: 31 May 2016

The 31 May case was expected to be influenced by pollutants from upwind regions (e.g., China) during the KORUS-AQ campaign (Peterson et al., 2019). To capture the impact of Chinese emissions from the observations, the DC-8 aircraft flew over the Yellow Sea (YS). The flight routes of the DC-8 during 31 May and the corresponding $\text{N}_\text{CN3}\text{–10}$ values are presented in Fig. 6a. During 31 May, substantial $\text{N}_\text{CN3}\text{–10}$ (~2000 cm$^{-3}$) was observed in the FT over the YS, and it even exceeded 5000 cm$^{-3}$ in the west of the SMA. In the time series of $\text{N}_\text{CN3}\text{–10}$ during 31 May (Fig. 6c), $\text{N}_\text{CN3}\text{–10}$ showed peaks at around 30,000–40,000 cm$^{-3}$ during the flight in the FT, reflecting the occurrence of SPF event. About 0.006 km$^{-1}$sr$^{-1}$ of backscatter coefficient was measured in the 2–3 km range under the influence of submicron particles formed in the FT (not shown).

Based on these observations, 31 May was designated as the FT SPF case. Fig. 7 displays the time series of the secondary inorganic aerosols and their precursors during the FT SPF case. Generally, the $\text{SO}_2$-to-sulfate conversion seemed to highly influence the particle formation events in the FT because the sulfate concentration was changed along with the $\text{SO}_2$ mixing ratio. On the other hand, the $\text{NO}_2$ mixing ratio and nitrate concentration were nearly zero, suggesting that oxidation of $\text{NO}_2$ had little correlation with the SPF event on 31 May. Because the baseline level of the $\text{SO}_2$ mixing ratio is typically low in the FT, a high SOR would be derived even if only a small amount of $\text{SO}_2$ was converted to sulfate or an abrupt variation in the $\text{SO}_2$ mixing ratio was induced by transport, degrading the meaning of SOR. For the FT SPF case, the sulfate-to-CO ratio was used instead of SOR because CO which has a relatively long lifetime is appropriate for tracing the change in sulfate (Ding et al., 2015). The sulfate-to-CO ratio had a positive
correlation with both the temperature and RH, indicating that aqueous-phase pathways as well as gas-phase reactions might be attributable to the sulfate formation in the FT (Fig. 8). Many studies reported that aqueous-phase oxidation of SO$_2$ associated with the uptake processes on the surface of preexisting particles is the main pathway of sulfate formation, although the gas-phase reactions of SO$_2$ are significant as well (Khoder, 2002; Tsona et al., 2018; Liu et al., 2020b); these findings are consistent with the results herein.

Due to the lack of continuous observation of atmospheric pollutants at high altitudes, the direct derivation of the general properties of SPF events in the FT during the entire KORUS-AQ campaign was limited. Rather than generalizing, investigation of the possible cause of the FT SPF case was conducted by simulating the behavior of SO$_2$ at 700 hPa using a chemical transport model (GEOS-Chem; Fig. 9). The migration of SO$_2$ and sulfate was simulated at the 700-hPa pressure level. The mixing ratio of the transported SO$_2$ over the YS was expected to be maximum around 12:00 LST on 31 May, implying that the FT over the YS during 31 May could be suitable for the active sulfate formation. When the continental precursors are directly transported over the shallow marine boundary layer, the formation of particles could be facilitated in the FT under favorable conditions such as the lack of the preexisting particles and increase in the sunlight (Takegawa et al., 2020). The submicron particles produced by this mechanism can spread to FT or be entrained to the BL, thereby also having an influence on the air quality at the
This observation-based capture of FT SPF resulting from continental condensable vapors above shallow marine boundary layer was consistent to the formation of new particles in the FT over open seas derived from the Hydrological cycle in Mediterranean Experiment (HYMEX) project (Rose et al., 2015).

4. Summary and conclusions

We conducted a comparative analysis of the processes associated with the SPF events that occurred in the BL and the FT during the KORUS-AQ campaign (May–June 2016). Several key findings are as follows:

- \( \text{N}_{\text{CN3}-10} \) generally decreased with increasing altitudes, reaching 7606 ± 12,003 cm\(^{-3}\) in the daytime BL. In addition, the number density of particles with diameters from 10 nm to 15 nm was over \( \sim \)10,000 cm\(^{-3}\) near the surface. Vertical distribution of nucleation-mode particles indicated that SPF occurrence around the Korean Peninsula during the KORUS-AQ campaign was mostly observed in the BL.
- For the BL SPF event over SMA, a major secondary inorganic species responsible for the SPF event was estimated to be nitrate. A positive correlation between NOR and temperature implied that gas-phase reactions of NO\(_2\) with OH or O\(_3\) possibly induced nitrate formation. From the relationship between NOR (or SOR) and \( \text{N}_{\text{CN3}-10} \) (\( > \)10,000 cm\(^{-3}\)), the relative importance of nitrogen oxidation grew as the \( \text{N}_{\text{CN3}-10} \) increased.
- \( \text{SO}_2 \)-to-sulfate conversion seemed to highly influence the FT SPF event over YS. Gas-phase and aqueous-phase pathways were thought to be participated in the sulfate formation, as indicated by positive correlation of sulfate-to-CO ratio with both temperature and RH. The production of high level of \( \text{SO}_2 \) by the transport from upwind regions above the shallow marine boundary layer might be attributable to...

Fig. 7. Same as Fig. 3, except for the dataset for the FT SPF case (31 May 2016). The period of FT (2 km–4 km) flight over the YS is shaded as azure colour.

Fig. 8. The scatter plot for sulfate-to-CO ratio versus (a) temperature and (b) relative humidity for DC-8 flight in FT over the YS during the FT SPF case (31 May 2016). The linear regression lines are represented as red solid lines. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)
the sulfate formation under the favorable conditions for the SPF in the FT.

Through the understanding of the SPF in the FT as well as BL inferred from the observations in this study, the calculation of formation rate in current schemes of the atmospheric models can be improved by taking these observed formation processes into account. Because SPF can be an effective pathway for CCN production (Rose et al., 2017; Gordon et al., 2009), radiative processes associated with the cloud properties would be understood better based on the improved schemes in future studies.

Acknowledgments

The authors are grateful to the NASA DC-8 pilots and crew, and to all members of the KORUS-AQ science team for their contributions during the field campaign and the agencies operating the surface networks. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT)(No. NRF-2021R1A4A5032520).
